ABSTRACT

Evidence continues to emerge that cancer is not only a disease of genetic mutations, but also of altered mechanobiological profiles of the cells and microenvironment. This mutation-independent element might be a key factor in promoting development and spread of cancer. Biomechanical forces regulate tumor microenvironment by solid stress, matrix mechanics, interstitial pressure and flow. Compressive stress by tumor growth and stromal tissue alters the cell deformation, and recapitulates the biophysical properties of cells to grow, differentiate, spread or invade. Such a solid stress can be introduced externally to change the cell response and to mechanically induce cell lysis by dynamic compression. In this work we report a microfluidic cell-culture platform with an integrated, actively-modulated actuator for the application of compressive forces on cancer cells. Our platform is composed of a control microchannel in a top layer for introducing external force and a polydimethylsiloxane (PDMS) membrane with monolithically integrated actuators. The integrated actuator, herein called micro-piston, was used to apply compression on SKOV-3 ovarian cancer cells in a dynamic and controlled manner by modulating applied gas pressure, localization, shape and size of the micro-piston. We report fabrication of the platform, characterization of the mechanical actuator experimentally and computationally, as well as cell loading and culture in the device. We further show use of the actuator to perform both, repeated dynamic cell compression at physiological pressure levels, and end-point mechanical cell lysis, demonstrating suitability for mechanical stimulation to study the role of compressive forces in cancer microenvironments. Finally, we extend cell compression applications in our device to investigating mechanobiologically-related protein and nuclei profile in cyclically compressed cells.

Keywords: Microfluidics, Mechanical actuation, Polydimethylsiloxane micropiston, Cell compression, Cancer biomechanics, SKOV-3

1   INTRODUCTION

24   Extensive efforts have been made to study the role of gene mutations in cancer and an accumulation of
25   multiple mutations has been proposed as being necessary for cancer development. Recently however,
26   evidence has been accumulated indicating that cancer is not only a disease of genetic mutations, but that
27   the micro- and nano-environments of cells may be essential factors in triggering tumor growth Bissell
28   and Hines (2011). For example, the dysfunctional collagen crosslinking in the extracellular matrix (ECM)
29   have been found to lead to breast tumorigenesis and modulate the ECM stiffness to force focal adhesions,
30   integrin expression and, in turn, breast malignancy Levental et al. (2009). Inevitably, tumors can initiate
31   due to an induction either from tumor microenvironment or genetic and epigenetic background of the
32   cells Bissell and Hines (2011). However, metastasis is the main cause of deaths in cancer patients, thus
33   recent research is elaborating on the basis of metastasis and potential treatments Mehlen and Puisieux
34   (2006). Tumorigenic and metastatic events are induced by mechanical forces from the altered cell and ECM
35   mechanics Bissell and Hines (2011); Shieh (2011); Tse et al. (2012); Polacheck et al. (2013). Biomechanical
36   forces regulate tumor microenvironment by solid stress, matrix mechanics, interstitial pressure and flow
37   Shieh (2011). Cancer cells alter their own biophysical properties and exert physical forces during primary
38   tumor growth and then to spread, invade or metastasize Polacheck et al. (2013); Wang et al. (2016). All
39   these examples point to that phenotype may become dominant over genotype of the tumor cells depending
40   on the microenvironment Bissell and Hines (2011). Thus, an altered mechanobiological profile of the
41   cells and microenvironment (a mutation-independent element) is proposed to be necessary to promote
42   development and spread of cancer Evans et al. (2019). However, there is no coherent quantitative data on
43   the nature and level of mechanical forces that influence the interactions between the physical micro- and
44   nano-environment and cancer cells Wang et al. (2016).

45   As a result, the application of mechanical compression on living cells, such as cancerous Tse et al. (2012);
46   Kalli et al. (2019a); Kim et al. (2007); Cheng et al. (2009); Takao et al. (2019); Kalli et al. (2019b); Kim
47   et al. (2017); Chen et al. (2017); Luo et al. (2019); Novak et al. (2020); Kim et al. (2019); Li et al. (2020),
48   non-cancerous and stromal cells Paggi et al. (2020); Ho et al. (2018); Kalli et al. (2018), neurons Hosmane
49   et al. (2011) and chondrocytes Lee et al. (2018), has gained importance in recent years. Compression
50   applied on cancer types, such as breast Tse et al. (2012); Luo et al. (2019); Kim et al. (2019); Li et al.
51   (2020), brain Kalli et al. (2019b), pancreatic Kalli et al. (2019a) and ovarian Novak et al. (2020); Asem
52   et al. (2020) cancer cells, resulted in more invasive and metastatic forms. While indicative, previous studies
53   all point out the need for further investigations to understand the effect of compressive mechanical stimuli
54   in metastasis of different cancer types, for example ovarian cancer Novak et al. (2020); Asem et al. (2020);
55   Bregenzer et al. (2019). Ovarian cancer cells are exposed to compressive stress mainly by tumor growth,
56   native tissue and hydrostatic pressure from the ascites Asem et al. (2020); Bregenzer et al. (2019). SKOV-3
57   is among the ovarian cancer cell lines tested to be responsive to compressive stimuli and has metastatic
58   phenotype. Thus, SKOV-3 cells can be used as a model to understand the impact of the compression
59   in epithelial ovarian cancer with intraperitoneal metastatic dissemination induced by direct extension
60   of cells and multicellular aggregates into the peritoneal cavity Klymenko et al. (2018). Understanding
61   these compressive forces may eventually help with the development of pharmaceuticals for the signal
62   transduction mechanisms associated with the mechanical stimulation, Kalli et al. (2019a) and mechanical
63   treatment Takao et al. (2019); Jain et al. (2014) or mechanoceuticals.

64   From a cell-biology perspective, mechanical compressive stress can induce the necrosis mode of cancer
65   cell death, resulting in autolysis. Such phenomena play important roles in the recruitment of immune
66   cells to the site of cancer through the release of danger-associated molecular patterns during necrosis

67 Takao et al. (2019). Compression also alters the cell deformation and causes mechanical lysis of the
68 cells. In general, controlled mechanical lysis of adherent cells *in vitro* has advantages over chemical lysis
69 by lytic agents or electrical lysis by applied electrical fields. Intracellular contents can be retained in
70 the sample after mechanical lysis and rapid cell-based assays can be run after compression Kim et al.
71 (2007). Compressive force induction *in vitro* further allows to study stromal cell differentiation and their
72 activation to cancer-associated form (e.g. fibroblast-to-myofibroblast differentiation) depending on the
73 magnitude of the applied stress Shieh (2011); Kalli et al. (2018). Controlled compression in particular
74 can be readily achieved in microfluidic settings. Microfluidic systems can be designed to have integrated
75 physical structures introducing static and dynamic physical inputs, as well as gradients, and enabling
76 real-time imaging, thus providing very useful tools to study biomechanics of the living cells.

77   While force application systems capable of inducing compressive stress on living cells exist in literature
78 Tse et al. (2012); Kim et al. (2007); Hosmane et al. (2011); Lee et al. (2018); Hsieh et al. (2014), only a
79 very limited number have yet been used to apply compression on cancer models in a localized, flexible and
80 dynamic manner. Tse *et al.* developed a transmembrane pressure device applying compression on cancer
81 cells; however, this is a bulk system that can apply constant force, lacking automation of modulation of the
82 applied pressure Tse et al. (2012). Similar static setups in bulk systems were used more recently by Kim *et*
83 *al.* Kim et al. (2019) and Li *et al.* Li et al. (2020) on cancer associated stromal cells. Compression can be
84 also applied on cells indirectly with the usage of multicellular spheroids (MCSs) and methods that can
85 restrict the volume of the MSCs. Delarue *et al.* Delarue et al. (2014) added dextran, a biopolymer that does
86 not penetrate single cells, to the culture medium of the MSCs. This change in the media exerted a moderate
87 osmotic stress on the outermost layer of the cells in spheroids. This osmotic stress was mechanically
88 transmitted to the rest of the spheroid as a compressive stress, which in turn resulted in a reduction of the
89 MCS volume. Thus, the compressive stress transmission on the cells inside the spheroids has an osmotic
90 origin but not a contacting physical surface by more rigid polymers such as polydimethlysiloxane and
91 an actively applied pressure, although this osmotic effect does not refer to high osmolarity, such as of
92 salts, acting at single cell level. This type of compression was also applied in a static and bulk manner in
93 48-well plates with the resultant compression at 5 kPa and 10 kPa based on the concentration of the dextran
94 added to the culture medium, unlike a controlled manner that can be achieved in microfluidic devices.
95 Although compression effects on other cell types, such as fibroblasts, neurons, chondrocytes, have been
96 shown using microfluidic devices, compression effects in cancer on-chip need more investigation. Lee *et*
97 *al.* mentioned dynamic compression; however, their study did not expand on the dynamic compression
98 capability of their devices Lee et al. (2018). While crucial to the latter, retraction and position recovery
99 of the compressed compartment of the device were not shown. Similarly, none of the previous studies
100 demonstrated well-defined pressure supply and sensing methods for automation, readability and portability
101 of the pressure application, or showed live compression on cells in real-time.

102   Asem *et al.* Asem et al. (2020) and Klymenko *et al.* Klymenko et al. (2018) applied static compression
103 at ~3 kPa and at 3.18-3.53 kPa, respectively, on ovarian cancer models in off-chip settings. On the other
104 hand, a recent work by Novak *et al.* remains the only study to date using a bioreactor device, which
105 is yet at millimeter scale, to investigate the effect of compressive mechanical stress on ovarian cancer
106 Novak et al. (2020). OVCAR ovarian cancer cells were exposed to both static and cyclic compression,
107 leading to increases in proliferation, invasive morphology and chemoresistance. When compared to cyclic
108 loading, static compressive stimulation enhanced the aspect ratio of the OVCAR3 cells, but no difference in
109 cellular proliferation could be observed. This results is of particular interest, as chronic mechanical loading
110 has been postulated to aid in ovarian cancer progression, forming a positive feedback loop Bregenzer
111 et al. (2019). Clearly, the effects of cyclic compression require further study and applied cyclic pressures

112 need to be expanded from the range of 3.9 to 6.5 kPa used by Novak *et al.* Novak et al. (2020) to the
113 physiologically-relevant 3.7 to 18.9 kPa and above estimated to occur in human tumors Bregenzer et al.
114 (2019); Jain et al. (2014).

115 Our system achieves the flexible, localized and dynamic control of such compression by use of a
116 polydimethylsiloxane (PDMS) actuator monolithically fabricated as attached to a membrane. The integrated
117 flexible actuator, herein called micro-piston, can be used to apply compression on cells in a dynamic
118 and controlled manner by modulating amount and duration of the applied gas pressure; shape and size
119 of the actuator; and its localization at x-y-z plane as suspended in the microchannel (Fig. 1). Localized
120 compression of the culture can be achieved by applying compression on cells under the micro-piston as
121 test group, while leaving the cells around the micro-piston non-treated as control group (Fig. 1(a)). This
122 provides the flexibility of having the test and control group in the same microchannel with a spatial and
123 temporal control on the groups. For instance, the same device can be first control and then both test and
124 control by applying dynamic compression, as well as that stains or antibodies can be loaded to do further
125 analysis on the cell groups at the same time. Thus, control group in this work refers to the cells under and
126 around static (non-compressed) micro-piston before dynamic compression, and the cells in the control
127 regions around the micro-piston after compression. Further, the dimensions of the compartments do not
128 rely on each other by photoresist master fabrication, as each PDMS layer is fabricated separately and
129 then assembled together (see Fig. S1). Thus, when a compartment of the micro-piston device needs to be
130 changed, it is enough to change dimension of one layer while keeping the others as the same.

131 In this study, we report the development of the microfluidic platform, detailed fabrication method and
132 mechanical characterization of the actuation mechanism by optical imaging methods and computational
133 simulations. We use the mechanical modeling which is in a good agreement with the experimental data
134 obtained from the vertical displacement measurements to predict the actual pressures inside the device
135 based on the externally applied pressures. We further show evaluation of the platform with SKOV-3 ovarian
136 cancer cells for mechanical stimulation and lysis under dynamic compression. We investigate cell viability
137 response to varying pressures in ascending order. We prove the ability of our platform to apply cyclic
138 and varying compression profiles sequentially so that it can be used to mimic the chronic mechanical
139 stimuli the cells are exposed to in ovarian cancer metastasis. We also show the temporal evolution of
140 the dynamic pressure control on cell compression and deformation with different pressure amounts, time
141 length and cyclic mode. We further extend the applicability of the cyclic compression with our platform
142 by capturing the actin and nuclei deformation in the cyclically compressed cells. Our results demonstrate
143 suitability of the micro-piston device for mechanical stimulation with various physiological pressures based
144 on live-and-dead cell assay and mechanobiologically-related protein profile to study cell-biomechanics and
145 compressive forces in cancer microenvironments.

2 MATERIALS AND METHODS

2.1 Device design and fabrication

147 To demonstrate localized and dynamically controlled compression of cancer cells we fabricated a
148 microfluidic platform with flexible actuators composed of PDMS Onal et al. (2019). Main components of
149 the platform are control channel in the top layer, membrane and micro-piston in the middle, and cell culture
150 chamber in the bottom layer enclosed with glass substrate (see Fig. 1(a)). Control channel was designed
151 to introduce external pressure Unger et al. (2000); membrane to enable micro-piston actuation; and the
152 micro-piston itself to apply compressive forces on the cells cultured on the glass surface in the bottom

153 layer channel. Photolithographic masks were designed using L-Edit (v2019, Mentor Graphics) and written
154 onto photomask blanks (Nanofilm, USA) using a laser mask writer (μPG101, Heidelberg Instruments).
155 Silicon wafers were dehydrated at 185°C in an oven overnight. After cooling down, the wafers were plasma
156 cleaned at 100 W with O_2 gas flow at 5 sccm for 10 minutes (Tergeo, PIE Scientific). As shown in Fig.
157 S1(a), dry-film lamination of negative-tone photoresist on silicon wafers was used to fabricate masters Sun
158 et al. (2018). For the lamination set-up we used 500 μm thick metal shims for a total thickness of Si wafer
159 plus 200 μm or 300 μm SUEX film (DJMicrolaminates) and PET sheet. The films were laminated to the
160 substrate at 65°C at 1 ft/min using a roll laminator (Sky 335R6, DSB). Post-lamination bake was applied
161 at 65°C for 15 minutes and the laminates were left to cool down for 2-3 hours before UV exposure on a
162 mask aligner (MA-6, SUSS). Filtered doses (PL-360-LP, Omega Optical) of 1800 mJ/cm^2 for 200 μm thick
163 film and 2300 mJ/cm^2 for 300 μm thick film were used in multiple cycles of 20 second exposures with 60
164 second cool-down intervals between cycles. Post-exposure bake (PEB) was applied at 65°C for 5 minutes
165 and at 95°C for 15 minutes for 200 μm films and 20 minutes for 300 μm films with a ramp up of 100°C/hr
166 and ramp down of 15°C/h. The masters were developed 24 hours after cooling down from PEB. Developer
167 was applied with the SUEX master face-down in Propylene glycol methyl ether acetate (PGMEA, Sigma)
168 until fully developed. Hard-bake was applied at 125°C for 60 minutes with a ramp up of 100°C/h and ramp
169 down of 15°C/h on hotplate.

170   Before replication, master molds were treated with 1H, 1H, 2H, 2H-Perfluoro decyl triethoxysilane
171 (PFDTES, Sigma-Aldrich) for 3 hours. All flexible layers of the micro-piston device were fabricated from
172 a 10:1 w/w mixture of PDMS (Sylgard 184, Dow) base and curing agent. Micro-pistons, monolithically
173 integrated onto a PDMS membrane, were obtained by spin-coating (Laurell WS-650) PDMS pre-polymer
174 onto 200 μm thick photoresist masters. After spinning, PDMS was baked for 1 hour at 80°C for initial
175 curing. Similarly, bottom layer channels and the control layer were fabricated by exclusion molding Jo
176 et al. (2000), modified for our work, and replica molding of PDMS Qin et al. (2010) off 300 and 200
177 μm thick photoresist masters, respectively. For the exclusion molding, the PDMS poured on the master
178 was first vacuumed for 2 hours, then a PE sheet was rolled on the PDMS and most of the excess PDMS
179 was excluded out. Finally, a rubber sheet and heavy metal block were placed on the PDMS on master
180 for complete exclusion out of the photoresist mold and the construct was baked at 80°C for 2 hours, as
181 shown in Fig. S1(a). Left to cool down overnight, the PDMS stamp with open channels and open frame
182 alignment marks was peeled off. Alignment marks designed to fit each other were used to align the layers
183 while bonding (see Fig. 1(a-c) and Fig. S1). After plasma surface treatment at 15 W with O_2 gas flow at 3
184 sccm for 1 minute (Tergeo, PIE Scientific), devices were assembled by manual alignment and bonding of
185 the membrane with micro-piston to the control layer and bottom channels (see Fig. 1(c-d)). PDMS layer
186 alignment was checked using a light microscope and, if necessary, corrected for fine matching the edges of
187 top and bottom microchannels before the plasma treated surfaces were permanently bonded. After every
188 alignment and bonding of the layers, the construct was baked for 2 hours at 80°C. These fabrication steps
189 were applied for different diameters and shapes including the circular, triangle and square micro-pistons
190 shown in Fig. 1(e). Those reference geometries were used to test our fabrication method for the resolution
191 of the structures at high dimensions of our device and high fidelity of the spin-coating method to obtain the
192 micro-pistons as monolithically attached to the membrane at these high dimensions of the micro-piston to
193 be fitting and suspending in a bottom channel height at mammalian cell culture standards and the thickness
194 of the attached membrane itself.

2.2   Mechanical modelling of micro-piston actuator

Actuation by the micro-piston device as a function of applied gas pressure were modelled as a symmetrical 3D geometry using COMSOL Multiphysics (V5.5, COMSOL). PDMS was modelled as hyperelastic material using a Saint Venant-Kirchhoff model. The Lame parameters λ and μ of PDMS were set at 4.66 MPa and 460 kPa, respectively Li et al. (2019). Borosilicate from the materials library was used to model the glass substrate as linear elastic material. External gas pressure was applied as a boundary load and varied from 0 to 700 mbar in 40 steps using a parametric sweep. The standard stationary solver was used with a physics-controlled mesh. Pressure under the piston was visualized as surface plot, and piston displacement and maximum piston pressure were exported as a function of applied gas pressure.

2.3   Pressure supply unit and operation of the force application system

Membrane, and thus micro-piston, were actuated by syringe pump (NE-1000, New Era Pump Systems) or pressure controller (OB1 Mk3+, Elveflow) coupled with pressure sensors (MSP4, 7 bar, Elveflow) and sensor readers (MFR and MSR, Elveflow) operated via ESI software (v3.02, Elveflow Smart Interface) to address the air or N_2 gas pressure amount required to deflect the membrane and actuate the micro-piston. While indicating the units of the pressure values in this work, mbar was used for the externally applied pressures as per the settings and calibrations on the pressure pump and sensor readers while kPa was used for the piston contact pressure as conversion from pascal by N/m^2 computed on the mechanical modelling. PDMS devices were fixed through a custom-designed, 3D printed (MoonRay, SprintRay) sample holder stage so that the devices did not move while applying pressure.

2.4   Optical profilometer measurements

The membrane deflection and micro-piston movements were quantified using a Profilm3D optical profilometer (Filmetrics Inc., USA) by scanning the total height of the vertical displacement of the deflected membrane and micro-piston during actuation. The data was further processed and analyzed using the ProfilmOnline software. For each applied pressure amount, average step heights of the vertical displacements were calculated from different regions-of-interest (ROIs) on the membrane at each side of the micro-pistons. For the full view of a micro-piston per cell-culture chamber, 3D optical profile series were scanned and stitched on an area of 7 mm height x 9 mm width with 20% overlap between individual scans (see Fig. S2(c)).

2.5   Cell culture and preparation

SKOV-3 ovarian cancer cells (supplied by the Laboratory for Cell and Protein Regulation at the University of Otago) were cultured in Earle's salts and L-Glutamine positive MEM medium (GIBCO®) supplemented with 10% fetal bovine serum (FBS, Life Technologies), 1% of penicillin/streptomycin (Life Technologies) and 0.2% fungizone (Life Technologies) in a humidified atmosphere of 5% CO_2 at 37°C. Cell seeding densities of 0.5M, 1M, 1.5M and 1.8M cells/ml for ovarian cancer cells were tested for optimization of the cell number in microfluidic channel to form a cell monolayer and capture cells under the micro-piston. To promote cell adhesion by enhancing electrostatic interactions between the cell membrane and the glass substrate, the cell culture channels of the microfluidic devices were coated with 0.01% (w/v in H_2O) poly-L-lysine (PLL) solution (Sigma).

2.6   Confocal imaging of the micro-piston device

For confocal imaging of the compression application with the PDMS micro-piston, PDMS cell culture channels with the suspended micro-piston inside were stained with DiD (lipophilic carbocyanine DiIC$_{18}$(5)

236 solid) (Vybrant, Thermo Fisher, 1:300) for 48 hours. The DiD solution on-chip was replenished 24 hours
237 after the staining started. The stained micro-pistons and microchannels were imaged using a confocal laser
238 scanning microscope (Leica TCS SP5) with PMT detectors. DiD was excited using the HeNe laser at 633
239 nm with 46% intensity with an emission at 665 nm. The distance between the bottom glass surface and
240 suspended micro-piston in the cell culture channel was 3D scanned at static state (before compression)
241 and then at compressed state of the micro-piston (see Fig. 2(d)) by taking the outmost upward z-position
242 of the 20X objective (NA 0.70; PL-APO IMM CORR) as reference for the start level of each scan by the
243 physical restraint of the mechanical knob at an inverted microscope setup. The length of each 3D scan
244 was taking up to 5 minutes by 5 μm step-size for a ∼300 μm total z-volume with the DiD and brightfield
245 channels at 1024x1024 resolution, due to the dimensions of the micro-piston device. In between the static
246 and compressed states, xyt (time-lapse) imaging mode of the laser scanning was applied to capture the
247 displacement of the actuated micro-piston while approaching the focal plane of the cells at the bottom
248 surface. Data were processed using the 3D Viewer plug-in of ImageJ (Fiji) Schindelin et al. (2012).

2.7   Device operation for cell culture and compression experiments

250 Before the cell culture on-chip started, micro-piston devices were sterilized under the UV light in a
251 biological cabinet for 30 minutes. Different cell-seeding densities were tested to improve cell density
252 on-chip and the chance of capturing cells under the micro-pistons, as described above. For the homogeneity
253 of cell distribution on-chip and capture under micro-piston, the way of loading cells into the microchannels
254 with those hanging structures was further optimized. Cells were introduced into the culture channels while
255 the micro-piston was either at static state or further driven-up (retracted) towards the control channel. In
256 our piston-retracted method, the micro-pistons were retracted by applying negative pressure by 2 cm^3 air
257 sucked over 4 minutes using syringe pumping system. Cells were introduced into the bottom channel and
258 the micro-piston was kept retracted for 5 minutes to let the cells sink to the PLL-coated glass surface. Then
259 the micro-piston was released to recover its position by applying positive (increasing) pressure. Cells were
260 cultured in the micro-piston devices for at least 2 days and their growth and spread around and under the
261 micro-pistons were monitored and recorded during culture until mechanical compression was applied.

262 Mechanical compression was applied to cells in their growth culture media to eliminate any non-
263 mechanical stresses such as impact of variable protein concentrations on cells. The microscopy focal
264 plane was kept on the cells while applying the compression and during movement of the micro-piston
265 towards the cells. Micro-piston movement, compression on cells and mechanical lysis of the cells were
266 recorded with time-lapse imaging. Data of the pressure sensor read was recorded during the compression
267 experiments to monitor the pressure profile in the devices and ensure the devices were working properly.
268 Compression was applied up to 640 mbar over 6 minutes. Cells were kept compressed for 1 hour and the
269 withdraw-rate applied for the position recovery of the micro-piston was the same as the compression rate.
270 For cell viability imaging, the cells were incubated with 2 μM EthD-1 and 4 μM Calcein AM solutions
271 of cell viability/cytotoxicity kit (Invitrogen) for 20 minutes. After the compression experiments, cells
272 were fixed on-chip with 4% Paraformaldehyde (Alfa Aesar) for 30 minutes and nuclei were stained with 1
273 μg/ml Hoechst solution (Thermo Scientific, 33342) for 20 minutes. Cell actin was stained with CF 488A
274 Phalloidin (Biotium, 1:40) for 1.5 hours.

2.8   Green fluorescent protein solution displacement by membrane deflection in the micro-piston device

277 Green fluorescent protein (GFP) was expressed in-house in *E. coli* bacteria. Micro-piston devices were
278 loaded with GFP solution (6.83 mg/ml) and compression was repeated as described for the cell experiments.

279 Thus, firstly, cells were cultured in the channel. Then culture media was replaced with GFP solution for
280 fluorescence imaging at the time of the compression. Micro-piston movement and membrane dynamics
281 were visualized for inference of the physical state from fluorescence intensity change (Fig. S3(a)). Using an
282 inverted microscope, the GFP time-lapse fluorescence images were taken under constant light exposure at 1
283 minute intervals of the actuation by the applied pressure amounts in Fig. S3(b-c). An A-A' line was drawn
284 at the region under the micro-piston and the plot profile of the GFP intensity change at each time-lapse
285 frame was shown for the A-A' line at the applied pressures (Fig. S3(b)). The plot profile for the GFP
286 intensity change under the membrane was shown along a representative line B-B' on each frame taken
287 at the corresponding pressure amount (Fig. S3(c)) similar to the work of Kim *et al.* on characterization
288 of PDMS membrane deflection with fluorescein Kim et al. (2007). Further, ROIs were drawn at different
289 regions adjacent to the micro-piston under the membrane. Mean gray values were measured from the GFP
290 intensity at those ROIs on the frames taken under the pressures of 0 mbar and 640 mbar for the ratio of
291 the mean gray value at static (non-compressed) to the one at the compressed form (see Supplementary
292 Table T1). This ratio was used for further correlation of the change in GFP intensity with the change in
293 compartmental heights of the micro-piston device during membrane deflections. At least 3 independent
294 experiments with different devices were performed to measure fluorescent intensity change as a result of
295 the displacement of GFP during actuation of the micro-piston in a typical cell experiment setup.

2.9 Imaging and data analysis

297 Images of cells were taken as phase-contrast time-lapse image series using a diascopic and epi-
298 fluorescence inverted microscope (Nikon ECLIPSE Ts2) equipped with a digital camera (Tucsen USB2.0
299 H Series) and TCapture imaging software. For cell growth, alignment and spread analysis, cells were
300 imaged day-to-day starting from the cell seeding time using 10X (NA 0.25; Ph1 ADL) and 20X (NA 0.45;
301 Plan-Fluor OFN22 Ph1 ADM) objectives. For dynamic cell compression experiments, data recording was
302 started at the same time as the pumping for applying the gas pressure and time-lapse images were captured
303 at every 10 seconds. Cells in the control regions where there was no micro-piston were also imaged before
304 and after compression application. Cell viability images for the cells under micro-piston and at control
305 regions in the channel were taken with Calcein AM and Ethidium homodimer-1 (EthD-1) epi-fluorescence.

306 Recorded images were processed and analyzed using ImageJ (Fiji) Schindelin et al. (2012). For cell
307 viability analysis, the cells under a micro-piston were determined according to the images with Calcein
308 AM and EthD-1, and cross-checked with the phase-contrast images taken before the deflection and the
309 time-lapse frames recorded during the deflection. Calcein AM stains the live cells at all-over the cell
310 membrane and cytoplasm while EthD-1 dye stains the dead cell nuclei only. With exception of the cells
311 with strong signals of Calcein AM or EthD-1, further analysis was done as follows: If the cell body was
312 under the micro-piston before compression, but totally burst after compression, and had no stain of Calcein
313 AM with or without traces of EthD-1, those cells were counted dead. If any cell had Calcein AM signal and
314 traces of EthD-1 signal at the same time, such cells were counted as damaged but alive, as well as the cells
315 with traces of Calcein AM and without any EthD-1 signal. Video frames recorded during deflection and
316 retraction of the membrane were used to track the cells bursting due to compression, as well as the changes
317 in their morphologies. In this correlation, if there are cells that do not give signal at the fluorescence images
318 captured after compression but exist on the phase contrast images captured before compression and during
319 time-lapse imaging of the compression, those cells were also added to the analysis during validation process.
320 Cells that were detached from the culture by attaching to the micro-piston surface during compression
321 were counted into the analysis by taking max intensity of the Z-projection of fluorescence images from
322 the glass and PDMS surfaces that came into contact. Two hundred fold magnification images of EthD-1

323 epi-fluorescence contained the most information for the stained nuclei of the dead cells fitting the region
324 under micro-pistons, and were thus used in the cell viability analysis. Thus, cell viability analysis relied on
325 cell counting by the fluorescence imaging with Calcein AM and Ethidium homodimer-1 (EthD-1) dyes.
326 Nuclei staining was also convenient to cell counting with Hoechst staining for total cell nuclei and EthD-1
327 staining for dead cell nuclei. ImageJ (Fiji) was used for counting cells by analyze particles function applied
328 on the threshold images with EthD-1 and Hoechst signals, or after adjusting the threshold of the Calcein
329 AM signal. Regions of interest (ROIs) were drawn around the micro-piston and cells that remain within
330 that ROI were counted as under micro-piston and the rest were counted as control as non-compressed cells
331 at all-over the region adjacent to the micro-piston. All the cells in the field of view (FoV) were counted as
332 total cells. Cell count at the region adjacent to micro-piston were determined by the subtraction of the cell
333 count under the micro-piston from the total cell count. The percentages of the live and dead cells were
334 calculated according to the cell counts.

335 In the next set of experiments with sequential cyclic compression on cells, the cell viability state
336 determination was slightly different than the discrete counting as live and dead cell, such that it was done
337 comparatively as a function of the applied pressure in ascending order within the same device. Cells were
338 categorized as live, damaged, highly damaged, and dead. For this comparative analysis, shape descriptors,
339 such as square, triangle, line, and circle, were assigned to cell viability categories of live, damaged, highly
340 damaged, and dead, respectively. They were drawn and tracked manually across the frames acquired at
341 each applied pressure, and determined depending on to which extent the cells where stained with Calcein
342 AM or EthD-1 as explained above. Manual tracking for determination of the cell viability state was applied
343 to the cells under the micro-piston only.

344 For the analysis of cell nuclei deformation, ImageJ (Fiji) was used to extract the regions of interest (ROIs)
345 for the cell nuclei boundaries by analyze particles function applied on the threshold images with Hoechst
346 epi-fluorescence signals. Then, the ROIs obtained from the Hoechst-stained cell nuclei were checked with
347 the corresponding phase contrast image for validation of the nuclei segmentation. Area, circularity, and
348 aspect ratio of the cell nuclei were measured from the ROIs. Two hundred fold magnification images were
349 used during the analysis of Hoechst stained nuclei in control (non-compressed) cells under micro-piston
350 and control regions (CR) around the micro-piston versus in compressed cells under micro-piston.

351 One-way analysis of variance (ANOVA) and Student's t-test were used to determine significances for the
352 comparisons of cell viability between multiple groups and between two groups, respectively. Student's
353 t-test was also used to determine the statistical significance of cell nuclei deformations. Two sample t-test
354 between percents (StatPac) was used to compare the percentages of individual groups in on-chip cell
355 distribution data. Statistical significance was taken as $p < 0.05$. Data were represented as mean $\pm$ standard
356 error of mean (s.e.m.), except for Fig. S4, in which the data is presented as mean $\pm$ standard deviation (σ)
357 for the PDMS membrane thicknesses measured with the optical profilometer.

3 RESULTS AND DISCUSSION

358 The phenotype of cancerous cells changes in response to applied dynamic compressive stress. Parameters
359 such as cell growth, morphology, viability and mechanobiologically-related protein profile are all affected
360 by mechanical stimulation and compression. Compression is unique for ovarian cancer and caused by
361 several primary sources. Both, growth-induced stress from the aberrant cell proliferation, displacing the
362 native cell populations, and external stress, stemming from the native tissue, have been identified as
363 noteworthy contributors to the compressive stress Bregenzer et al. (2019); Jain et al. (2014). Moreover,

364 hydrostatic pressure by the excess fluid and ascites expose ovarian cancer cells to additional compressive
365 forces Netti et al. (2000), although this factor, depending on the volume of ascitic fluid, largely varies
366 among ovarian cancer patients. Collectively, these stresses evidence that compression has a paramount
367 importance in shaping the mechanobiology of ovarian cancer. To study the role of compression in detail,
368 compressive stress needs to be applied to cells in a localized, flexible and controlled manner. The lab-on-a-
369 chip platform introduced in this work achieves this by use of a PDMS membrane actuator with attached
370 micro-piston. PDMS is well suited for mechanical actuators due to its high elasticity and the very low drift
371 of its properties with time and temperature Schneider et al. (2008). Our platform is composed of a control
372 microchannel in a top layer for introducing external force and PDMS membrane with monolithically
373 integrated micro-pistons suspended in a bottom microchannel. This piston was used to apply mechanical
374 compression on ovarian cancer cells cultured on the glass surface enclosing the bottom layer (Fig. 1).
375 Dynamic cell compression in this work points out the capability of the micro-piston device to dynamically
376 compress the cells at various profiles and durations for a wide range of applications. At each application,
377 the duration and mode of the dynamic compression was given at the associated figure and writing. Before
378 use with cells, mechanical parameters of the device were characterized via micro-piston actuation to
379 ensure repeatability of compression. A summary of the characterization of different compression profiles
380 is given in Figure 3. The characterization of the micro-piston actuation was done using optical imaging
381 methods and two different external pressure system types, adding flexibility based on the laboratory
382 requirements. The mechanical modeling in a good agreement with the experimental data obtained from
383 the vertical displacement measurements was used to predict the actual pressures inside the device based
384 on the externally applied pressures. Bottom channel loading with cells and the culture of cancer cells
385 in the micro-piston device was optimized experimentally. This was followed by the use of the device to
386 study compression at physiologically-relevant pressure levels and mechanical lysis of cells. Cell viability
387 response was investigated at sequentially applied profiles and varying pressures in ascending order. The
388 proven ability of our platform to simulate cyclic and varying compression profiles shows that it can
389 be used to mimic the chronic mechanical stimuli the cells are exposed to in ovarian cancer metastasis.
390 Detailed time-lapse live cell imaging showed the temporal evolution of the dynamic pressure control on
391 cell compression and deformation with different pressure amounts, time length and cyclic mode. The
392 applicability of the cyclic compression with our platform was further demonstrated by capturing the actin
393 and nuclei deformation in the cyclically compressed cells. Actin stress fibers showed distinct deformation
394 in the samples with applied pressures in ascending order. While the compressed cell nuclei were changed
395 for their circularity at different pressures, their areal and axial deformation were not permanent at milder
396 pressures such as 12.5 kPa and 17.9 kPa, unlike at higher pressures such as 20.7 kPa, for 1 hour-long cyclic
397 compression.

3.1 Characterization of the micro-piston actuation

399 Characterization of PDMS device geometries, membrane deflection and thus micro-piston actuation
400 was performed by 3D profilometry and confocal microscopy (Fig. 2). For 3D profilometry, the devices
401 were not covered by a glass surface to enable formation of the optical interference on PDMS surfaces.
402 Also, no cells and media were included in the measurements. For confocal microscopy, the devices were
403 bonded to glass, and bottom channels with micro-pistons were loaded and stained with DiD solution.
404 The confocal measurements were performed either with or without cells and their culture media. Vertical
405 displacement was measured as a function of applied pressure for membranes of different thicknesses. These
406 were obtained by varying PDMS spin-coating and vacuum conditions to better understand the impact
407 process variability may have on piston actuation and ultimately, cell compression. We found that the time

408 length the PDMS mixture was kept under vacuum after mixing (until spin coating) affected the thickness
409 of the membrane, in particular when slower spin-speeds were used (see Fig. S4). Membrane thickness
410 increased observably for spin-speed of 500 rpm when the vacuum time after mixing was extended from
411 35 to 90 and 150 min. This effect was not observed for the higher spin speed of 1000 rpm, even after 150
412 min of degassing, which indicates a correlation with the pot life (the time required for viscosity to double
413 after mixing the base and curing agent) of Sylgard 184 being >120 minutes Corning (2008). It is also
414 important to note that when the vacuum duration after mixing was kept as little as 25-35 minutes, not all of
415 the micro-pistons could be recovered from the 200-μm height photoresist master on a 4-inch Si wafer due
416 to insufficient degassing time. In contrast, a 100% yield could be regularly obtained when spin-coating at
417 more than 1-hour vacuum durations from the time of mixing.

418   To characterize membrane deflection and micro-piston actuation, vertical displacement measurements,
419 obtained via optical profilometry, were used to quantify the deflection of 100, 215 and 345 μm thick
420 membranes selected from the spin-coatings with thickness range of 102 $\pm$4.3, 211 $\pm$14.8, 343 $\pm$27.4
421 (mean $\pm\sigma$), respectively, as monolithically fabricated with 300 μm diameter pistons (Fig. S5). The pressure
422 applications and membrane deflections were applied by using two independent pressure systems, pressure
423 controller system (Fig. 2(a-b) and Fig. S5(a-b)) or syringe pumping system (Fig. 2(a and c) Fig. S5(c-d)).
424 By the two application systems, the vertical displacements of the micro-pistons with thicker, 215 and
425 345 μm, membranes were linear compared to thinner, 100 μm, membrane with 50-mbar or 0.5-cm^3 air
426 increments up to 250 mbar applied pressure. In essence, this novel micro-piston device allows using a wide
427 range of membrane thicknesses. However, vertical displacement amount depends on the applied pressure
428 magnitudes and in a final shape of the device it is also restricted by the gap between the micro-piston
429 and bottom surface. Additionally, the pressure magnitudes that can be applied and sensed during the
430 micro-piston actuation still relies on the pressure controller capability and readability of the pressure
431 sensors in use. Thus, in design, the bottom channel total height and the micro-piston height determines
432 the gap which also needs to suit cell culture needs. Membrane thickness to be used in the micro-piston
433 device can be selected based on the designed gap and the range of external pressure application and precise
434 sensing. Taking all into account, for the devices used for cancer cell compression experiments in this study,
435 the average membrane thickness was measured as 211 $\pm$14.8 (mean $\pm\sigma$) μm (n = 164 optical profiles
436 from 7 spin-coatings), where the PDMS was kept under vacuum at 650-700 mmHg for 1.5 hour from
437 mixing (including the 1 hour while PDMS is on the photoresist master) and spun at 500 rpm for 30 s
438 (Fig. S4). In addition to characterizing the dimensional fidelity of fabricated masters and PDMS replicas
439 (Table T2), compartmental heights of the assembled micro-piston devices were measured for channel total
440 height and micro-piston heights before the device was bonded to glass. To facilitate this, the gap between
441 the micro-piston and bottom surface was calculated for each device by measuring the step height from
442 the leveled surface of the sides of the channel to the surface of the suspended micro-piston in 3D optical
443 profiles (see Fig. S2). Values of the difference between the total height and gap showed close agreement
444 with measured micro-piston height values, illustrating the reliability of the measurements and data analysis
445 for the characterization of the compartments of the micro-piston devices.

446   Next, characterization of the 215 μm thick membrane deflection with applied higher pressures was
447 followed by micro-piston actuation in an open device to demonstrate position recovery. Figure 3(a)
448 shows the actuation sequence used to measure deflection. Pressure loading profiles were applied using
449 either a pressure controller system (Fig. 3(b)) or syringe pumping system (Fig. 3(c)) and membrane and
450 micro-piston position was found to fully recover to the starting position within measurement limits. This
451 demonstrates that our device can be used for automated dynamic compression and cyclic compression with
452 a pressure controller system. Figure 3(c) in particular, shows that, if no pressurized gas supply is available

453 or a more portable solution is required, semi-automated compression can be performed with a syringe
454 pumping system with an almost identical membrane displacement behavior.

455   The concept of applying compression in a fully enclosed device was illustrated using confocal imaging of
456 the PDMS micro-piston stained with DiD cell tracker. This stain was chosen as it allows for simultaneous
457 imaging of PDMS structures and cells Kajzar et al. (2008). Images were taken before compression and
458 while the micro-piston was compressed with the cell experiment settings, as shown in (Fig. 2d). Staining
459 and confocal imaging were able to visualize the micro-piston position inside the device, however, we found
460 the process too slow to capture the dynamic compression on cells, mainly due to the large dimensions
461 of the micro-piston compartment (Fig. S2(a-b)). This result is in agreement with others in literature on
462 confocal microscopy being slow for the real-time volumetric capture of the dynamic compression Lee et al.
463 (2018). Thus, to facilitate the use of wide-field microscopy for imaging the dynamic processes in the device,
464 membrane and micro-piston movement was monitored via the displacement of green fluorescent protein
465 (GFP) reporter solution in the micro-piston chamber, as shown in Fig. S3. Again, the same compression
466 profile was applied as in the cell experiment settings and fluorescence intensity change during deflection of
467 the membrane was recorded via time-lapse images. As illustrated by the images in Fig. S3(a), micro-piston
468 touch-down could be tracked (also see Movie V1) and related to device areas where no GFP was present,
469 such as chamber and channel walls. Residual fluorescence signal observed under high pressures (640-1415
470 mbar, Fig. S3(b)) was attributed to the cells cultured on the glass surface, whereas no cells and no GFP
471 solution was present for the background region corresponding to the PDMS sides of the channels. In Figure
472 S3(a), the indicated PDMS sides adjacent to the microchannels were used for background measurements.
473 While the vertical displacement of the micro-piston in channel was controlled via the membrane, little
474 change in the GFP signals under the micro-piston was observed for pressures above 640 mbar (Fig. S3(b)).
475 Thus, at higher pressures, the micro-piston was no longer being displaced vertically and the mechanical load
476 was being stored in the compression of the micro-piston itself. On the other hand, the flexible membrane
477 attached to the micro-piston continued to be displaced downwards as evidenced by the GFP solution volume
478 and hence fluorescence signal under the membrane around the micro-piston decreasing with increasing
479 applied pressure (Fig. S3(c)). Compared up to 860 mbar, the pressure values in Fig. S3(b-c), which were
480 read in the fully enclosed devices through the sensory feedback connected within the air flow circuit, were
481 matching the pressure values read during the membrane deflections within the open devices, where the
482 optical profilometry was used (Fig. 3(c)). Optical profilometry and fluorescence solution displacement
483 data was further cross-correlated for three independent devices, as shown in Table T1, demonstrating
484 measurement consistency among devices and between techniques. While recording the GFP images, the
485 focal plane was kept fixed on the cells, as would be the case in cell compression experiments. The average
486 mean gray value ratio obtained in this way was 1.39. If the same experiments were run with images taken
487 at different focal planes of the GFP solution for maximum intensity of a z-stack of fluorescence images,
488 this ratio would be closer to the average height ratio of the devices, which is 1.57. Nonetheless, the data
489 demonstrates that, in lieu of ultra-fast confocal imaging, fluorescent reporter displacement could be used to
490 track piston movement in real-time during cell compression experiments.

491 **3.2   Cancer cell loading and culture in micro-piston device**

492   Following mechanical characterization, cancer cell growth and cell viability on the microfluidic platform
493 were investigated by running control and test experiments, either on separate devices or sequentially on
494 a single device. For the optimizations of cell distribution on-chip and cell capture under micro-pistons,
495 devices were loaded with cells either while the micro-pistons were in static state with no external pressure,
496 or driven-up (retracted) towards the control channel with an applied negative pressure of 342 mbar (-342

497 mbar) as read by the pressure sensor (Fig. S6(a)). Cell capture under micro-pistons was determined to be
498 on average 9 cells per 0.07 mm^2 for piston-in-static-state loading and increased more than 3-fold to 28 cells
499 per 0.07 mm^2 for piston-retracted loading. Thus, due to favorable flow conditions in the piston-retracted
500 loading method, more cells were captured under the micro-pistons. Cell distribution on-chip was further
501 analyzed for piston-retracted loading. At zero time of the culture, 11.4% of the loaded cells per field of
502 view (FoV) of the microscopy images were under the micro-piston of 14.4% area of the FoV adjusted
503 with the micro-piston at the center (Fig. S6(b) and Table T3). The rest of the cells, 88.6%, were around
504 the micro-piston in the 85.6% area of the FoV. The percentages of cell number under and around micro-
505 piston were not significantly different than the percentages of the corresponding area (p = 0.1417). Thus,
506 homogenous cell distributions could be obtained in micro-piston chamber from the beginning of the cell
507 culture. The cell number under micro-pistons increased on average 83% from Day 0 to Day 1 and 44%
508 from Day 1 to Day 2, providing a confluent cancer cell monolayer under the micro-pistons. Thus, cells
509 grew under and around the micro-pistons at static state of the device regardless the height difference by the
510 gap between the micro-piston and bottom surface compared to rest of the channel (see Movie V2 and Fig.
511 S6(b)).

512   The lesser gap under the micro-pistons compared to the total height in the rest of the culture channel
513 (Fig. S2) may impact on nutrient supply to the cells. To account for this during mechanical stimulation
514 experiments, cells were kept in their cell-culture growth media to prevent any relative stress that might
515 emerge due to nutrient factors. Moreover, the heights of the cell culture channel (on average 313 μm), and
516 the gap between the bottom of the micro-piston and the cells on the glass surface (on average 108 μm)
517 were designed so that cells had access to nutrients in cell-culture growth media at static state by including
518 appropriate cell channel geometries Young and Beebe (2010). In particular, the design is expected to allow
519 for passive diffusion of the nutrients over time. In further applications, aim-specific biomolecular gradients
520 can be created from the ports of the bottom layer of the device towards the micro-piston inside the culture
521 channel to study the effect of the generated gradients on cells Keenan and Folch (2008).

522   As shown in Fig. 4(a), in static culture conditions cell viability was found to be 99.3% in the culture
523 channels, 99.2% in chambers for cells adjacent to the micro-pistons and 99.5% for those under the
524 suspended micro-pistons. These results demonstrate that the device has a cell-safe design and operation
525 until cells under the micro-pistons are compressed by application of high pressures (>300 mbar) to the
526 control layer.

527 **3.3 Compression application and mechanical deformation and lysis of the cells**

528   Dynamic application of compression on cell monolayers was demonstrated by deforming and lysing the
529 cells under the micro-pistons and comparing cell viability to control areas on the same device. Cell viability
530 was analyzed for control (non-compressed) devices and after compression with various micro-piston shapes
531 and dimensions. An example of a typical cell compression experiment is shown in Movie V3, where a
532 cell monolayer was first compressed and the micro-piston then retracted. All pressure values during the
533 compression were recorded using a pressure sensor located within the flow circuit before the gas flows
534 into the control microchannel to monitor the micro-piston position feedback in response to the applied
535 pressure. Sensor readings for the micro-pistons were consistent with each other over the length of the
536 experiments and all micro-pistons, including different diameters and different shapes, exhibited reliable
537 position recovery in cell experiments (see Fig. S7).

538   For in-depth analysis of cell viability on-chip a Calcein AM/EthD-1 cell viability/cytotoxicity kit was
539 used to monitor all the viable and dead cells. Figure 4(b) shows the dynamic compression on SKOV-3

cancer cells and mechanical lysis by the stained cell monolayers in control (non-compressed or before
compression) and compressed areas under micro-pistons of different shapes. When the membrane was
deflected and the micro-piston moved down onto the cells and burst them by compression, majority of the
cells lost their Calcein AM at the beginning of the 1 hour-long compression. Efflux of Calcein AM shows
that those cells were highly damaged as no fluorescence signal was gained, and hence could not be accepted
as viable anymore. The main reason of that the micro-piston was kept compressed for 1 hour is to show
how good the device is in operation of the long mechanical compressions, which was also recorded by the
pressure sensor in these cell compression experiments (Fig. S7). Cell counting for cell viability analysis
on-chip was achieved by optimizing a method of fluorescent label-dependent automated cell counting for
adherent cells by dead cell and total cell nuclei staining with Ethidium homodimer-1 (EthD-1) and Hoechst
dyes, respectively (Fig. S8(a)). Although cell counting was achieved in parallel with viability testing, by
staining both live and dead cells and adjusting the threshold on the images for Calcein AM and EthD-1
signals, respectively (Fig. S8(b)), this was further automated by counting the adherent cells via their stained
nuclei after validating the correct segmentation of the nuclei.

As shown in Fig. 4(a), in all groups, including control and after compression, cell viability in the channel
was calculated for the regions adjacent and under the micro-piston. In doing so, no significant differences
in cell viability were observed in control devices between the groups adjacent and under micro-pistons.
Additionally, in the regions adjacent to the micro-pistons no significant difference in cell viability in
control (non-compressed) and after compression was observed. However, after compression the cell
viability under micro-pistons became significantly different (p < 0.0001) to that of cells in non-compressed
regions in the same device chambers. Cell viability decreased from on average 99.4% to 25.8% under
the micro-pistons of 200, 250, 280 and 300 μm diameter circular, triangle, and square shapes after 1
hour-long compression with 640 mbar gas pressure. At the same time, no significant difference in cell
viability was observed for compression between different micro-piston types and sizes. As illustrated by
Fig. 4(b), any residual cell viability after compression was mainly due to the cells at the micro-piston
periphery, as those cells were being partially compressed, but not necessarily burst by the micro-pistons.
Thus, the mechanical compression and lysis of the cells by the micro-pistons in our devices were mainly
governed by the applied external pressure, in combination with the thickness of the membrane carrying
the micro-pistons. This consistency in operating the devices with different shapes of the micro-piston
can define the cell compression and lysis area into the culture as well as that the cell patterning can be
achieved in further tissue engineering applications. Hsieh *et al.* had varied the diameter of their circular
structures (i.e. hydrogel circles under buckled PDMS membrane) from 2 mm to 12 mm and thus changed
the compression effect on fibroblast cell alignment Hsieh et al. (2014). Lee *et al.* had also varied the
diameter of their circular structures (i.e. PDMS balloons) from 1.2 mm to 2 mm and observed no significant
differences in chondrocyte cell deformation between adjacent diameters (e.g. for 1.2 mm vs. 1.4 mm or 1.4
mm vs. 1.6 mm). They also observed no differences in cell viability between the control (without dynamic
compression) and dynamically compressed chondrocytes Lee et al. (2018). Comparatively, in our study,
the diameter range has been further downscaled to from 200 μm to 300 μm of circular micro-pistons. If
required, changes to the aspect-ratio of the micro-pistons could be used to alter the compression process
and hence, cell viability and biological responses of the cells.

Although the cell viability dyes are considered non-toxic at the low concentrations used, Probes (2005)
we also performed experiments to control for any possible effect of live/dead cell staining and phototoxicity
might have besides the mechanical compression. To do so, we compressed the cells after staining them
with cell viability dyes and checked the viability during the dynamic compression experiments (see Fig.
4(b)) while, on the other hand, we directly compressed non-stained cells and checked for the viability

585 after the compression (see Fig. S9 and Fig. S10). Results showed that, at 2 µM Calcein AM and 4 µM
586 EthD-1 concentrations, there was no significant effect of the dyes on the cells which were also treated
587 with the mechanical compression (p > 0.05). This demonstrates that the cell damage and lysis in our
588 results were mainly caused by the applied mechanical compression. Mechanical lysis is reviewed to be
589 advantageous over the other lysis methods for its high throughput and higher efficiency in lysing cells
590 Shehadul Islam et al. (2017). In this regard, our platform can apply to controlled release of the intracellular
591 components such as nucleic acids and proteins by adjusting the degree of the mechanical disruption of the
592 cell membranes under the micro-piston while also leaving the control cells around as intact.

593   Furthermore, we computationally modeled the actuation of the micro-piston device, where we established
594 a good agreement of the simulations with the experimental data obtained from the vertical displacement
595 measurements of the micro-piston with pressure controller and syringe pump systems (Fig. 5(a)). This
596 model was going to guide us on predicting the actual pressures inside the device based on the externally
597 applied pressures (Fig. 5(b)). We experimentally conducted dynamic cell compression to establish to which
598 extend cells were affected by the amount of applied pressure and the application time. For this, we applied
599 a sequence of cyclic compression profiles on SKOV-3 cancer cells at mild and then higher pressures in
600 a continuous manner (Fig. 6 and Movie V4). The pressure controller system was used for automation of
601 this cyclic compression application. First, a pressure amount ladder was formed up to 354 mbar, during
602 which the cells showed distinct deformation. Subsequently, cells were set to being chronically compressed
603 for 5 minutes at 354 mbar, followed by a rest for 5 minutes at 0 mbar, as indicated by the steps '1b-i,
604 2b-h' in Fig. 6(a). This cyclic compression was applied for a total of 1 hour. As can be seen from the
605 image sequence in Fig. 6(a), cells were physically deformed under the micro-piston when being cyclically
606 compressed throughout the cycles '1a-i' (cells at rest) and '2a-h' (cells compressed) (also see Movie V4).
607 The morphology of the compressed cells changed in response to micro-piston contact, with the nuclei and
608 membrane expansion observably different to that of the state before compression at '1a' of Fig. 6(a). In the
609 following compression profiles shown in Fig. 6(b), the application was continued with increasing pressures
610 from 370 and 400, to 640 mbar, respectively. Cells were compressed for up to 2 minutes at each of the
611 higher pressures, which was much shorter than the compression times used in Fig. 4. Cell lysis formed
612 at higher pressures, as expected (see Movie V4), and cell viability was monitored 10-15 minutes after
613 every pressure application profile was complete, allowing for an incubation time for the viability assay.
614 Results shown in '1i' of Fig. 6(a) and '1j-l' in Fig. 6(b) demonstrate that cells were mostly alive after the
615 first cyclic compression profile was complete ('1i'), despite being deformed distinctly throughout the 1
616 hour-long cyclic compression. Simulation of the mechanical actuation (see Fig. 5(b), Fig. S11 and Movie
617 V5) indicated that an actuation with 354 mbar gas pressure corresponded to a contact pressure of 15.6 kPa.
618 While the gap of 109 µm between the piston and glass surface was closing, piston contact pressure started
619 at 1.4 kPa by the applied pressure of 325.9 mbar. In next two of additional 1 mbar, it reached physiological
620 values of 3.6 and 4.5 kPa, and then the piston distinctly deformed cells at 15.6 kPa (Fig. 5(b)). This value
621 fell within the physiological ranges estimated for growth-induced (4.7 - 18.9 kPa) and external (3.7 - 16.0
622 kPa) compression Jain et al. (2014). The latter has been suggested to be a more noteworthy contributor to
623 the total perceived stress Bregenzer et al. (2019) and estimated to exceed 20 kPa based on the experimental
624 data from murine tumors Jain et al. (2014). Following this cycle, more cells were permanently damaged,
625 appearing as dead after step '1j' at 370 mbar (contact pressure of 23.8 kPa from simulation in Fig. 5(b)).
626 Other cells with traces of Calcein AM, but no trace of EthD-1 were considered as damaged but alive,
627 while the cells with traces of the both stains were considered as highly damaged. After step '1k' at 400
628 mbar (contact pressure of 37.8 kPa from simulation in Fig. 5(b)), only few cells remained alive, with the
629 rest dead. These results were expected, as this and following pressure levels exceeded the upper limits of

630 both estimated growth-induced and external stresses. Finally, apart from a few cells at the micro-piston
631 periphery, all cells directly underneath were dead after step '1l' at 640 mbar (contact pressure of 140
632 kPa from simulation in Fig. 5(b)). These viability results for short compression times at higher pressures
633 complement results of the 1 hour-long compression at 640 mbar in Fig. 4. As observed for this overall
634 long compression experiment, cells in control regions around the micro-piston remained alive at all times
635 during application of the cyclic compression profiles (Fig. 6). Responses of the cells under micro-piston to
636 varying applied pressures in ascending order from Mild (15.6-15.9 kPa) to Intermediate 1 (23.8-26.8 kPa)
637 to Intermediate 2 (37.8-51 kPa) to Severe (127.8-140 kPa) were summarized in Fig. 7. Additionally, the
638 vertical displacement from the position that the piston applied mild pressures on cells until severe pressures
639 bursting the cells, shown in the plateau of the main plot in Fig. 5(b)), is matching the height of the SKOV-3
640 cells, which is typically extending to around 3 μm Mann et al. (2005). Overall, the ability of our platform
641 to simulate cyclic and varying compression profiles shows that it can be used to further mimic the chronic
642 mechanical stimuli the cells are exposed to in ovarian cancer metastasis Bregenzer et al. (2019).

643   We further showed the applicability of the cyclic compression with our platform by capturing the actin
644 and nuclei deformation in the cyclically compressed cells. In contrast to the control group, actin stress
645 fibers showed distinct deformation in the samples with applied pressures in ascending order. At 20.7
646 kPa (an upper limit of physiological range), the signal for actin was gained mostly at the edge of the
647 cells, indicating exposure to a higher stress that distinctly deformed the cell cytoskeleton. Given the more
648 regular shape of nuclei, further analysis was conducted for cell nuclei deformations. Areal and axial cell
649 nuclei deformation after 1 hour-long cyclic compression at 20.7 kPa at live cell conditions were significant
650 between the compressed cells under micro-piston and non-compressed cells under the control micro-piston
651 and in the control region adjacent to the micro-piston (Fig. 8). No significant change was observed between
652 the compressed and control cells at 12.5 kPa (a mild physiological value) and at 17.9 kPa (an intermediate
653 physiological value) for areal and axial cell nuclei deformation (Fig. 8(b,d)). Circularity of the cell nuclei,
654 however, were significantly less in the compressed cells at all the applied pressures (12.5, 17.9 and 20.7
655 kPa) compared to the control group (Fig. 8(c)). These results propose that while the compressed cell
656 nuclei were changed for their circularity at different pressures, their areal and axial deformation were not
657 permanent at milder pressures such as 12.5 kPa and 17.9 kPa, unlike at higher pressures such as 20.7 kPa,
658 for 1 hour-long cyclic compression. Nucleus is a mechanosensitive organelle capable of responding to solid
659 stresses and the nuclear deformations we observed for the cells exposed to compression can impact the
660 activity of nuclear pore complexes and associated proteins, which in turn modulate the nuclear import of
661 transcription factors. Such nuclear perturbations can alter gene expression and induction of DNA repair
662 programs Nia et al. (2020). A detailed time-lapse live cell imaging of the compression recorded for ladder
663 pressure increase from 0 kPa up to 17.9 kPa (piston contact pressure from simulation) and a short cycle
664 at 17.9 kPa with gradual increase (from 0 kPa to 17.9 kPa) and decrease (from 17.9 kPa to 0 kPa) in 30
665 s for each, which then sequentially followed by 1 hour-long cyclic compression at 17.9 kPa showed the
666 temporal evolution of the dynamic pressure control on cell compression and deformation (see Movie V6).
667 This dynamic control points that although the deformed cells did not seem much affected at the very first
668 cycles by the beginning of the pressure ladder and mild compression, the time length and number of the
669 cycles of the dynamic compression made the cells morphologically different throughout the application.
670 The cell actin and nuclei deformations explained here were as result of the end point assay by such dynamic
671 compression control at the indicated pressures. Our study findings add to the results on plastic deformation
672 of the cells by Ho *et al.* who applied cyclic compression between 10 and 15 psi (68.9 kPa and 103.4 kPa)
673 by the pressure of the control valve at 0.5 Hz for 6 min and did not observe permanent plastic deformation
674 of the MCF10A normal breast epithelial cells Ho et al. (2018). Different pressure amounts, time length

675 and cyclic mode altogether affect the degree of plastic deformation cells can experience when exposed to
676 compression.

677   In summary, the platform was able to dynamically compress cell monolayers up to the mechanical lysis
678 of cells at actuation pressures above 300 mbar. By enabling similar experiments to be performed in a more
679 integrated fashion, our study results add to the previous work by Tse *et al.*, which showed that mechanical
680 compression can enhance the invasive phenotype of cancer cells and stimulate their migration Tse et al.
681 (2012). While pressure magnitudes obtainable with our system are comparable to those in work by Kim
682 *et al.*, who applied up to 35 kPa external compressive stress on MCF7 cancer cells up to lysis Kim et al.
683 (2007), the use of micro-pistons for compression in our system adds the advantage of non-compressed
684 regions for direct control on-chip. The importance of control was most recently demonstrated by Lee *et*
685 *al.*, who observed no significant difference in cell viability between compressed and control groups when
686 14 kPa of pressure was used to mechanically stimulate alginate-chondrocyte constructs Lee et al. (2018).
687 We further showed the capability of the platform to dynamically stimulate cancer cell monolayers with
688 various intermediate actuation pressures in a continuous, cyclic manner with an order of Mild (15.6-15.9
689 kPa) to Intermediate 1 (23.8-26.8 kPa) to Intermediate 2 (37.8-51 kPa) to Severe (127.8-140 kPa). As such,
690 the results shown here expand on the work by Hosmane *et al.*, who used intermediate pressures applied
691 statically by micro-pads to study the mechanics of neuronal cell damage Hosmane et al. (2011). Their
692 results showed single axon mild injury and regrowth at <55 kPa, moderate levels of injury from 55 to 95
693 kPa and severe levels of injury for pressures >95 kPa.

694   Finally, while cell compression with our micro-piston device was shown using ovarian cancer cell
695 monolayer mimicking the impact of compression on direct extension of cells into peritoneal cavity in a
696 metastatic dissemination of epithelial ovarian cancer, the overall device concept can readily be adapted for
697 use with cell-laden hydrogels or by loading a spheroid solution for compression of cells in 3D. The device
698 can be further used in its current form to apply external compression on an endothelial cell monolayer to
699 study the basics of the vessel compression existing in cancer patients, as shown in *ex vivo* tumor sections
700 Jain et al. (2014); Padera et al. (2004). In the future we hope to expand this work to the extended tumor
701 microenvironment including stromal cells, such as fibroblasts and macrophages. These have been reported
702 as sensitive to compressive forces, e.g. fibroblast-to-myofibroblast differentiation, and there are known
703 biochemical interactions between cancer cells and stromal cells, which might be triggered by the solid
704 stress in the microenvironment Shieh (2011).

4 CONCLUSION

705 We have introduced a flexible multilayer microdevice with a micro-piston suspended into cell-culture
706 chamber for dynamic mechanical cell stimulation and compression. Fabrication of the device was described
707 and actuation by a monolithic membrane controlled by a gas channel on the top layer was demonstrated.
708 We showed the characterization of the micro-piston actuation using optical imaging methods and two
709 different external pressure system types, adding flexibility based on the laboratory requirements. The actual
710 pressures inside the cell channel were computationally modelled based on the applied pressures and device
711 dimensions. Hence, our device is optimized to apply a whole range of physiological pressure levels, as
712 well as milder and severe pressures. Applicability of the device was demonstrated via the quantification
713 of the response of ovarian cancer cell monolayers to mechanical stimulation in the micro-piston device.
714 Cell viability before and after mechanical compression was used to illustrate the suitability of the platform
715 for cyclic cell compression and lysis. Circular, square, and triangular micro-piston outlines and different
716 diameters were successfully propagated into the cell layer. Using different micro-pistons, the results by

717 cell viability response suggest that our cell stimulation and compression application rely on the membrane
718 thickness and externally applied pressure amount, thus it is repeatable for a desired geometry of the actuator.
719 The proven ability of our platform to apply cyclic and varying compression profiles sequentially shows that
720 it can be used to mimic the chronic mechanical stimuli the cells are exposed to in ovarian cancer metastasis.
721 Detailed time-lapse live cell imaging showed the temporal evolution of the dynamic pressure control on
722 cell compression and deformation with different pressure amounts, time length and cyclic mode. The
723 applicability of the cyclic compression with our platform was further demonstrated by capturing the actin
724 and nuclei deformation in the cyclically compressed cells. Actin stress fibers showed distinct deformation
725 in the samples with applied pressures in ascending order. While the compressed cell nuclei were changed
726 for their circularity at different pressures, their areal and axial deformation were not permanent at milder
727 pressures compared to higher pressures for 1 hour-long cyclic compression.

728 Based on current studies and future perspectives, our platform provides a useful mechanical tool to study
729 the direct effect of compressive forces on cancer cells and the tumor microenvironment. It can be used
730 to investigate responses of cancerous and healthy cells to applied stress with regards to changes in cell
731 morphology, viability and mechanobiologically-related protein profile. Surface-coating solutions of natural
732 ECM such as fibronectin, laminin, or type 1 collagen can be used to enhance cell adhesion to the culture
733 surface in the microchannels by mimicking the native microenvironments. The platform is potentially
734 suitable for automated creation of wound healing assays on-chip, as the spacing between the micro-piston
735 and cell culture surface, together with the cell number captured under micro-piston can be tightly controlled.
736 Having different micro-piston shapes available will also be of interest in this application and in tissue
737 engineering in general. Overall, our platform constitutes a promising tool for studies of cell-mechanical
738 force interaction, as well as cell-cell, cell-microenvironment and cell-drug interactions, where single or
739 co-cultured cell types need to be patterned and controlled.

CONFLICT OF INTEREST STATEMENT

740 The authors declare that the research was conducted in the absence of any commercial or financial
741 relationships that could be construed as a potential conflict of interest.

AUTHOR CONTRIBUTIONS

742 SO conceived the study, designed and fabricated the device, carried out experiments, analyzed data,
743 prepared figures, and wrote the manuscript. MA co-supervised the study, and reviewed the manuscript.
744 VN conceived and supervised the study, acquired funding, ran simulations, edited figures, and wrote the
745 manuscript.

FIGURE CAPTIONS
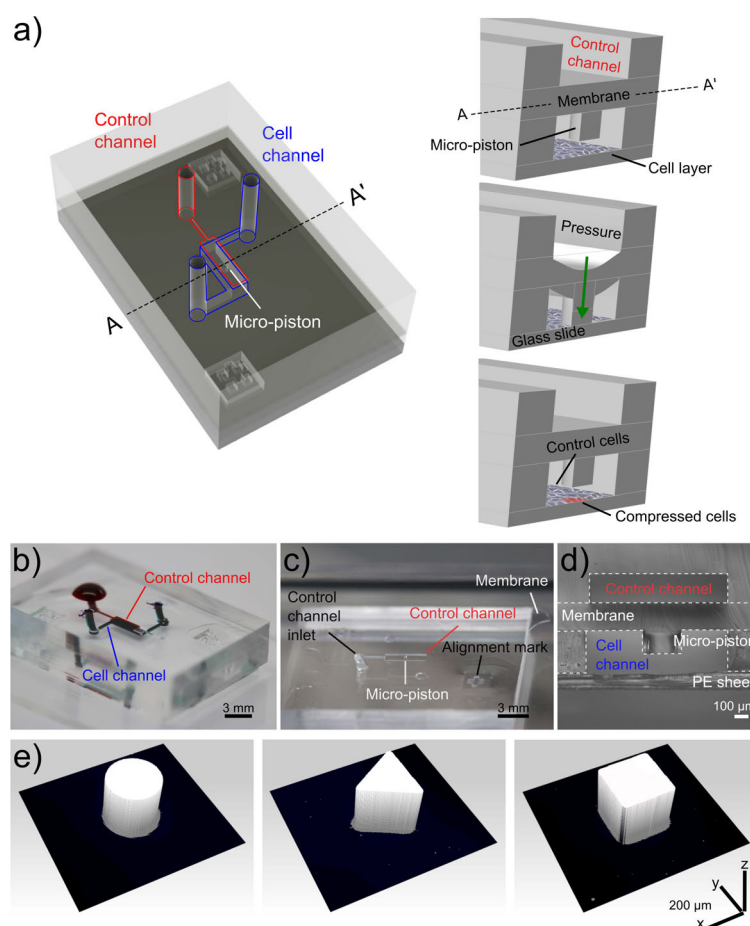

Figure 1. Device design, concept of compression on cells and fabricated devices. **(a)** Assembly design of the chip composed of control channel (outlined in red) for introducing gas pressure and cell channel (outlined in blue) for cell culture. The concept of applying compression on cells is illustrated by the membrane deflection and micro-piston brought onto the cells by the pressure applied through the control channel and retracted back after compression. Thus, the localized part of the cell monolayer under micro-piston was compressed while the rest acted as control (Figure not drawn to scale). **(b)** Top view of the PDMS layers of the micro-piston device (Scale 3 mm). The devices were vacuumed for 3 hours and channels were passively filled with dye solutions for visualization. **(c)** Top view of the PDMS micro-piston with the membrane bonded to control layer before bonding to bottom open channels (Scale 3 mm). **(d)** Cross-section view of the micro-piston device (Scale 100 μm). **(e)** 3D profilometer scans of circular, triangle and square micro-pistons sitting on PDMS membranes bonded to control channel layers as in (c) (x-y-z scale 200 μm each).
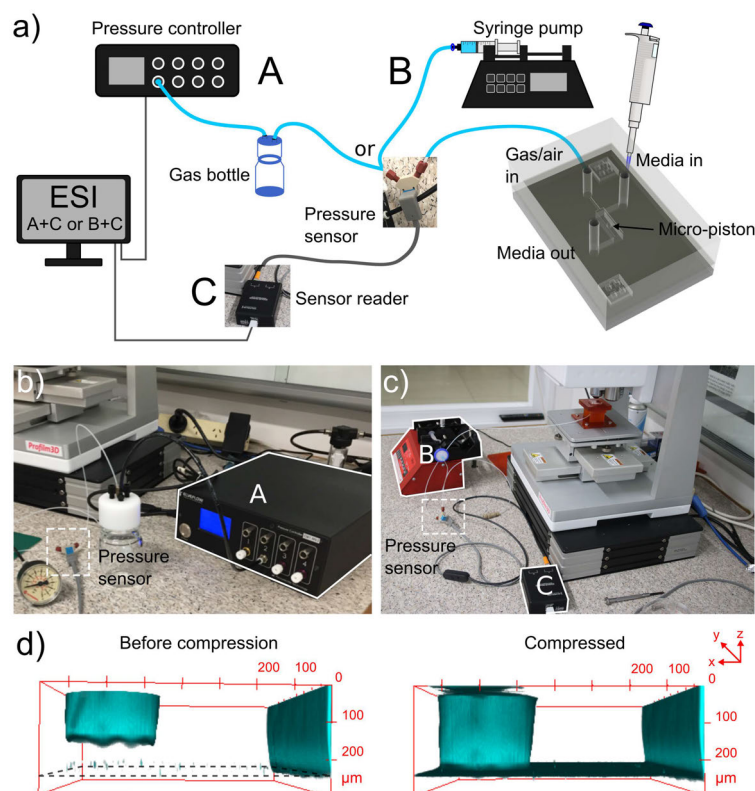

Figure 2. Pressure supply, sensing setup and confocal imaging of the micro-piston device compression. **(a)** Schematic of the experimental setup showing the ways of pressure supply into the control channel and cell seeding. Cells within media were introduced into the cell channel through the inlet labeled as 'Media in', and gas or air pressure was supplied through the inlet of the control channel labeled as 'Gas/air in'. The pressure sensor was located just before the gas flow into the control channel. **(b)** Experimental setup with pressure controller system. **(c)** Experimental setup with syringe pumping system. **(d)** Confocal images illustrating the concept of applying compression with an integrated PDMS micro-piston in a microfluidic channel. PDMS was stained with DiD for visualization.
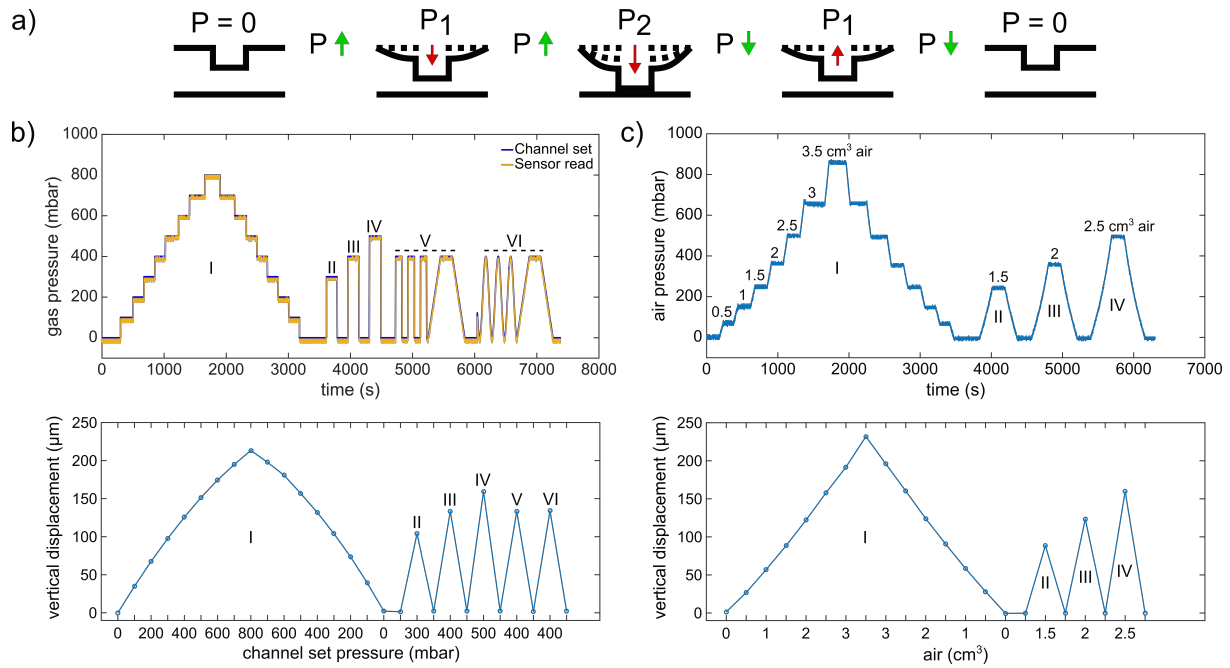

Figure 3. Circular micro-piston actuation using two different pressure application systems. **(a)** Schematic of membrane deflection and micro-piston actuation by the applied pressure. At static state of the device, there was no external pressure (P), P = 0. Vertical displacement of the membrane and micro-piston was measured while the pressure was kept constant at P = 0, P1 or P2. Membrane and micro-piston were actuated step-by-step by positive (increasing) pressure. Then, the applied pressure was decreased in the same manner of step-by-step and the displacement was measured at each decreased pressure for position recovery. Green arrows indicate when the pressure was increasing or decreasing in between the states. Red arrows indicate the direction membrane and micro-piston moved. **(b)** Micro-piston actuation with various pressure magnitudes and loading profiles (I-VI) for the 215 μm membrane attached to 300 μm diameter piston, generated by pressure controller system. In profile 'I', the pressures were positively or negatively applied step-by-step by 100-mbar increments and the displacement was scanned at each step. In profiles 'II', 'III', and 'IV', the pressures were applied suddenly and the displacement was scanned for each sudden pressure amount. In profiles 'V' and 'VI', cyclic compression where the membrane was deflected and retracted repeatedly was applied by an automated pressure application with (V) or without (VI) time intervals. On the pressure profiles graph, 'Channel set' is the pressure that was set through the pressure controller of the system while the 'Sensor read' is the pressure that was read through the pressure sensor connected to the gas flow into the control channel of the micro-piston device. **(c)** Micro-piston actuation with various air amounts leading to corresponding pressure magnitudes in the profiles I-IV for 215 μm membrane attached to 300 μm diameter piston, generated by a syringe pumping system. In profile 'I', the pressures were positively or negatively applied step-by-step by 0.5-cm^3 increments in air amount. The resulting pressures were read through the pressure sensors and the displacement was scanned at each step. In profiles 'II', 'III', and 'IV', the pressures were applied suddenly and the displacement was scanned for each sudden pressure amount.
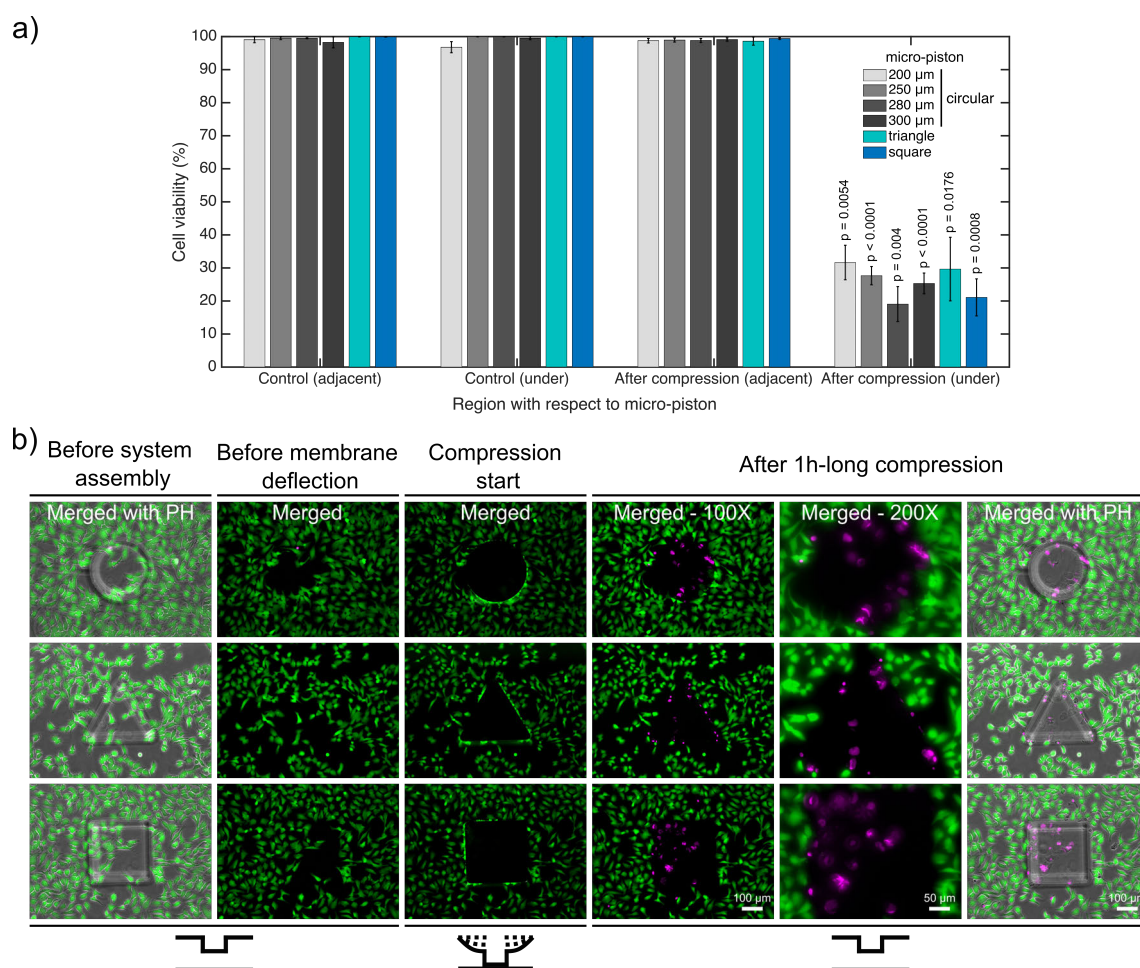

Figure 4. Cell viability for mechanical compression and lysis. **(a)** Cell viability decreased from on average 99.4% to 25.8% under the micro-pistons of 200, 250, 280 and 300 μm diameter circular, triangle and square shapes (1 h compression, 640 mbar) compared to non-compressed (control) devices (n = 25 devices at static state (non-compressed); n = 25 devices with dynamic compression). The cells within the periphery of the micro-piston, which had part of their body under the micro-piston area, were counted into the group of 'under the micro-piston'. All other cells in the field of view (FoV), outside of the micro-piston periphery, were counted as "adjacent to micro-piston". **(b)** Dynamic compression on SKOV-3 cancer cells, mechanical cell lysis and an illustration for patterning the cell monolayer by stamping the particular shape of the micro-piston as circular, triangle or square. Cells and their viability were monitored before the device was connected to the pressure supply unit of the compression system (1st column); before membrane deflection (2nd column); when membrane was deflected and compression started at 640 mbar (3rd column); after 1h-long compression was applied with different shapes of micro-pistons on SKOV-3 cells and micro-piston position was recovered (4-6th columns). After system assembly, and before membrane deflection and compression were started, the cell viability solution was replaced with cell culture media. Live cells retained their Calcein AM signal since the dye entered the cells and was hydrolyzed inside. Once the compression was complete and micro-piston was retracted to its initial position, the cell culture chamber was reloaded with cell viability solution for staining the dead cells. Live cells (green) and dead cells (magenta) were imaged with Calcein AM and Ethidium homodimer-1 (EthD-1) epi-fluorescence and merged with phase contrast images. Merged: merged form of the Calcein AM and EthD-1 epi-fluorescence images, Merged with PH: merged form of the epi-fluorescence images with the corresponding phase contrast (PH) image.
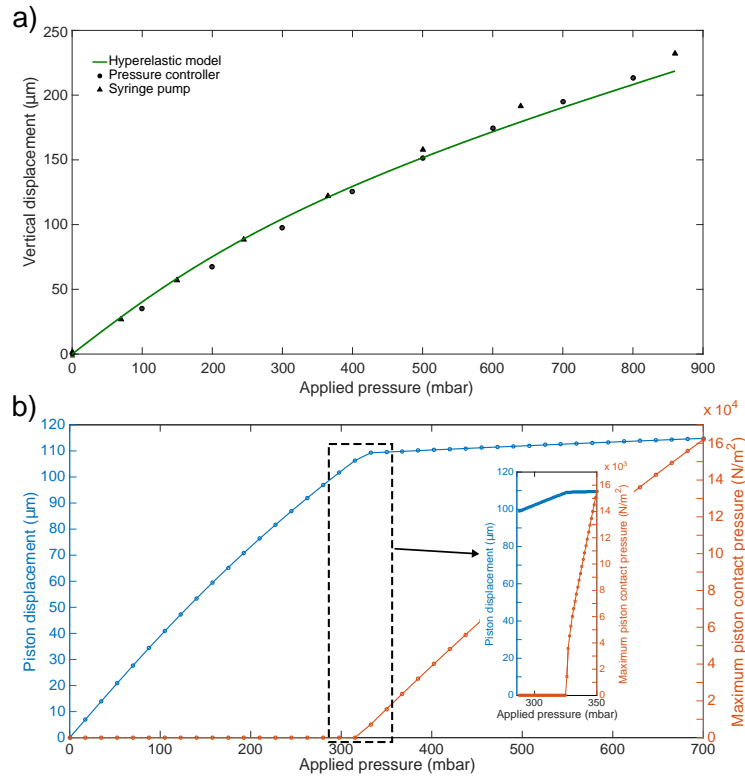

Figure 5. COMSOL simulation results for the actuation of the micro-piston device. **(a)** Experimental (•,▲) and computational (line) data comparison. **(b)** Plot of simulated vertical separation of the micro-piston top and the bottom glass substrate, and maximum contact pressure under the micro-piston as a function of applied gas pressure (boundary load). The applied external pressure was varied from 0 to 700 mbar in 40 steps in the main plot. The inset shows more data points of the initial stage of the piston maximum contact pressure formation at mild pressures, part of the simulation run from 0 to 350 mbar in 320 steps.
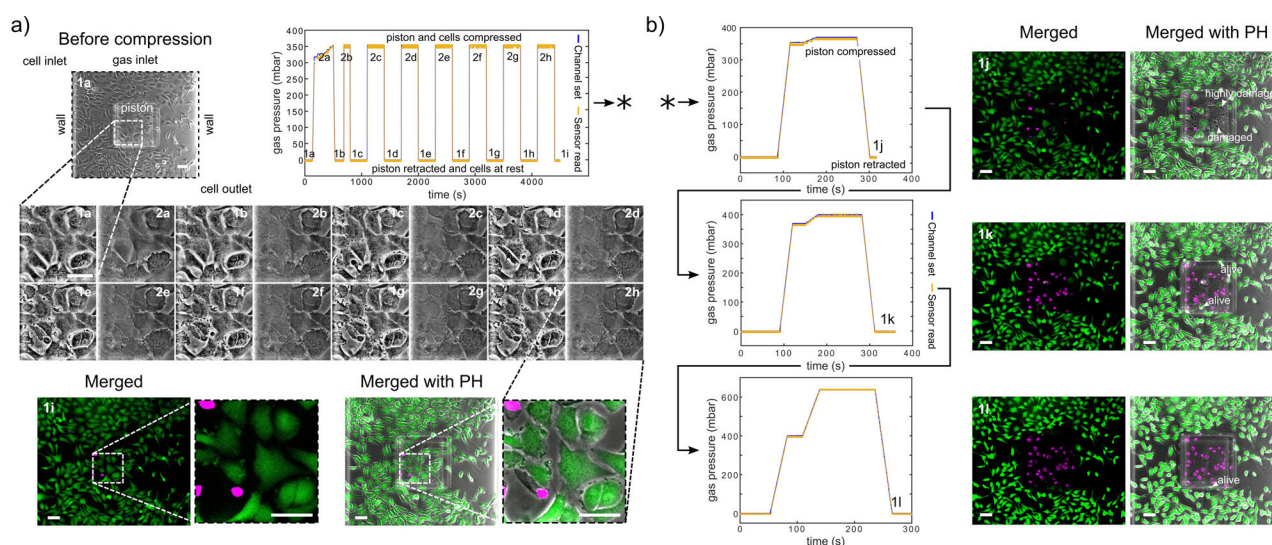

Figure 6. Continuous sequence of cyclic compression profiles applied to a monolayer of SKOV-3 cancer cells in a continuous manner. **(a)** Before compression image of the cells corresponds to step '1a' of the cyclic compression. In the first pressure profile, at step '2a', a pressure amount ladder was formed up to 354 mbar, during which cells showed distinct deformation. Subsequently, cells were chronically compressed for 5 minutes at 354 mbar, then rested for 5 minutes at 0 mbar (1b-i, 2b-h). This cyclic compression was applied for 1 hour. The close-up image sequence shows example cell shapes/deformations under the micro-piston while cells were compressed/rested throughout the cycles, with steps '1a-i' and '2a-h' corresponding to cells at rest and cells compressed, respectively. Cell viability was monitored 10-15 minutes after the pressure application profile was completed (1i). Live cells (green) and dead cells (magenta) were imaged with Calcein AM and Ethidium homodimer-1 (EthD-1) epi-fluorescence, respectively, and merged with phase contrast images. **(b)** Continuation (*) of the pressure application, with pressure increased to 370, 400, and 640 mbar, respectively. Cells were compressed for up to 2 minutes at each higher pressure. Arrow heads (in white) show the representative cells for viability state and cell damage as a result of gradually increasing compression during each corresponding pressure profile. (All scale bars 100 μm). Merged: merged form of the Calcein AM and EthD-1 epi-fluorescence images, Merged with PH: merged form of the epi-fluorescence images with the corresponding phase contrast (PH) image.
Figure 7. Summary of cancer cell response under micro-piston to varying applied pressures in ascending order from Mild (15.6-15.9 kPa) to Intermediate 1 (23.8-26.8 kPa) to Intermediate 2 (37.8-51 kPa) to Severe (127.8-140 kPa) out of at least 3 independent experiments of cyclic compression using micro-piston devices which were operated at a continuous manner of the applied pressure sequence.
Figure 8. Representative fluorescent microscopy images and analysis for actin and nuclei of cancer cells which experienced 1 hour-long cyclic compression in micro-piston device. **(a)** Control and compressed cell groups stained for actin (green) and nuclei (blue). Dashed areas are under micro-piston, while the surrounding is control region (CR). Merged: merged form of the Phalloidin (stain for actin) and Hoechst (stain for nuclei) epi-fluorescence images, Merged with PH: merged form of the epi-fluorescence images with the corresponding phase contrast (PH) image, Magnified: two hundred fold magnification images of the region under micro-piston indicated with the dashed area in the row of 'Merged with PH'. Representative arrows (white) show the distinct actin deformation by the increased fluorescence signals at the edges of the cells in the compressed groups under the micro-piston. Nuclei deformation in control (non-compressed) cells under static micro-piston and control region (CR) around micro-piston versus in compressed cells under micro-piston measured for area **(b)**, circularity **(c)** and aspect ratio **(d)** of the cell nuclei (mean $\pm$ s.e.m. n = 73, 63, 185, 71, 161, 74, 163, 92 cell nuclei). Dashed horizontal bars show significant differences between control region (CR) group and compressed group under micro-piston, in the same device as per each pair. Continuous horizontal bars show the comparison pairs among the groups under micro-piston.
